AGS Studies 0800-1100 3/5/74

Purpose: To activate the triple switch for passage through the transition energy.

Results: By the end of the period the triple switch phase jumps at transition are operating at intensities of up to  $6 \times 10^{12}$ . The amount of "transition loss" averaged  $\approx 10\%$  of the CBM reading. This is the normal amount at these intensities with only the single phase jump. Also the observed debunching was not significantly less than normal.

Comments: The time intervals between jumps was based on Lichten's calculations for  $\eta = 1.3$  (for the AGS an  $\eta_0 \approx 1.2$  at  $5 \times 10^{12}$  has been estimated) with the first jump assumed to be at transition. Time ran out before these values could be varied. Also the machine intensity was quite variable and comparisons would have been almost impossible.

It was necessary to clamp the radial error signal at the start and finish of the triple switch sequence. Thus while it could not effect the phase during the sequence it could still cause fluctuations in the first and third jump amplitudes. This mode of operation was better than the unclamped case or the case where the clamp bracketed the triple switch timing sequence.

This interaction with the radial loop will have to be minimized before a thorough test of the triple switch can be made. It results from the fact that due to bunch shape oscillations or intensity variations the radial error signal is not the same from pulse to pulse. When the sign of this signal is reversed at transition a corresponding phase jump occurs. Thus the total jumps will vary and the resulting phase ~~will~~ will not be correct during a radial expansion etc.

The first step will be to investigate the driving source of the intensity dependent bunch shape oscillations that take around 2.15 nsec and which the damping loop cannot completely control.
