Brookhaven National Laboratory  
July 1993

## Introduction

The shunt impedance of the rf accelerator cavities is measured using a beadpull test set. The method is based upon the field perturbation technique developed by Slater.<sup>1</sup> The perturbation of the electromagnetic fields caused by a metal or ceramic sphere as it moves along the axis of the cavity causes a small change in the resonant frequency of the cavity. The magnitude of this frequency shift, which can be measured to high accuracy, is proportional to the value of the square of the electric and magnetic field at the point of perturbation. A beadpull test set was developed and results were compared to computer models of a test cavity.

## Computational

The SUPERFISH subset of the Poisson codes were used to calculate the shunt impedance and Q of the test cavity. SUPERFISH calculates either TE or TM modes of axisymmetric cylindrical cavities based on the boundary conditions. The SUPERFISH results were used as a method of comparison for the data obtained from the beadpull test. SUPERFISH is quite accurate when dealing with the fundamental mode and with perfectly

axisymmetrical cavities. However, when the cavity symmetry is broken by either tuners, amplifiers, or mode dampers, the code results are no longer exact and another method is needed to measure the field distribution. The objective of the beadpull is to supplement our computational tools in determining shunt impedance and field patterns. This is especially true for transverse modes in asymmetric cavities.

The boundary conditions that delineated the physical regions inside the cavity was the input file for AUTOMESH. AUTOMESH creates a file called TAPE73 which is used for the LATTICE program. LATTICE fills the defined regions with an irregular triangular mesh that fits the boundaries of the cavity. SUPERFISH is the eigenvalue solver which calculates the resonant frequency and determines the magnetic field values throughout the mesh problem. The cavity boundary is shown in Appendix 1. The SUPERFISH output routine, SF01, accepts the input file and prints information about the properties of the cavity. All quantities appearing in the output of SUPERFISH are normalized by assuming that the average electric field on the axis is 1MV/meter. The SF01 output file contains the value of  $E_z$  at points on the axis, the values of moment integrals of  $E_z$  along the axis, and tables for each segment on which power and frequency calculations were sought. The SUPERFISH output postprocessor (Appendix 2) also provides us with the data we need to calculate  $R/Q$ .  $R$  is the shunt impedance and  $Q$  is the ratio of the time-average energy stored at a resonant frequency to the energy dissipated in one period of this frequency. According to SUPERFISH calculations, the shunt impedance and quality factor,  $Q$ , for the small scale model was 0.394543M $\Omega$  and 5716, respectively. The  $R/Q$  value was calculated as 69.02 ohms. This value of  $R/Q$  could now be used as a comparison in the bead perturbation test.

## BEAD PERTURBATION TEST

### Theory

The perturbation theory demonstrates that the introduction of a small body into a resonant electromagnetic cavity will change the frequency by an amount that is related to the size, shape, and material of the object and the values of the electric and magnetic fields of the cavity. There are two important conditions that must be remembered when applying the perturbation theory.<sup>2</sup> One, is that the theory is only applicable for infinitesimal perturbations, and strictly speaking cannot be applied for finite distortions. Second, the formulas about to be derived will not hold when any distortion is made from a situation not originally satisfying the boundary conditions. This is due to the fact that the perturbation formula is based on the unperturbed electric and magnetic fields satisfying the boundary conditions prior to the time when the perturbation is introduced. In practice, this method may be used as long as the perturbation is small and does not distort the fields patterns in the cavity.

The frequency shift due to the introduction of a perturbing sphere in an electromagnetic resonant cavity is derived by Papas<sup>3</sup> as:

$$\frac{-\delta \omega_0}{\omega_0} = \frac{3\mu_0 \frac{\mu_1 - \mu_0}{\mu_1 + 2\mu_0} H_0 H_0^* + 3\epsilon_0 \frac{\epsilon_1 - \epsilon_0}{\epsilon_1 + 2\epsilon_0} E_0 E_0^*}{4U} \Delta V$$

where  $\omega_0$  = resonant frequency

$$\epsilon_1 = \epsilon_0 \epsilon_r$$

$$\epsilon_0 = 8.85 \times 10^{-12} \text{ (F/m)}$$

$V$  = volume of the bead ( $m^3$ )

$U$  = total stored energy in cavity (J)

A perturbation consisting of a dielectric sphere introduced into the cavity affects only electric fields, and so one can neglect the magnetic field contributions. Therefore, for a ceramic sphere, the equation above becomes:

$$\frac{-\delta \omega_0}{\omega_0} = \frac{3\epsilon_0 \frac{\epsilon_1 - \epsilon_0}{\epsilon_1 + 2\epsilon_0} E_0 E_0^*}{4U} \Delta V$$

Since a perfectly conducting metal can be considered as having  $\mu_1=0$  and  $\epsilon_1=\infty$ , the frequency shift produced by a metal sphere is:

$$\frac{-\delta \omega_0}{\omega_0} = \frac{-\frac{3}{2}\mu_0 H_0 H_0^* + 3\epsilon_0 E_0 E_0^*}{4U} \Delta V$$

It should be noted that the frequency shift is proportional to the magnitude of the field strength and differs in sign for electric and magnetic fields. In order to determine magnetic field properties, it is necessary to use both dielectric and metallic spheres of equal size and subtract the data sets. Solving for the electric field of the ceramic sphere gives:

$$E = \left[ \frac{4U}{3\epsilon_0 \Delta V} \frac{\epsilon_r + 2}{\epsilon_r - 1} \frac{\delta \omega_0}{\omega_0} \right]^{1/2}$$

For a cavity of length  $l$  at power  $P$ ,

$$R = \frac{\left( \frac{1}{l} \int_0^l E dz \right)^2}{2P}$$

$$\text{Since } Q = \frac{2\pi (\text{stored energy})}{\text{energy loss/cycle}} = \frac{\omega_0 W}{P}$$

then  $R/Q$  for the ceramic sphere can be found with the following equation:

$$\frac{R}{Q} = \frac{2}{3\epsilon_0 \omega_0^2 l \Delta V} \frac{\epsilon_r + 2}{\epsilon_r - 1} \left( \int_0^l \sqrt{\delta \omega_0} dl \right)^2$$

## Setup

The beadpull test on the cavity was done once with a metal sphere and again with a dielectric sphere. The sphere was brought through the cavity fields on a nylon monofilament which was suspended in a loop over four small reels. The tension in the monofilament was kept very taut in order to minimize sagitta and the amplitude of vertical vibrations. A very important fact to note is that this monofilament does not affect the fields in the cavity. One of the reels was driven by a motor in order to keep the velocity of the sphere constant. The bead would move through the entire gap, stop, and then return to its original position along the same center axis. The resonant frequency of the cavity was

found using a network analyzer. In the case of our test cavity, the resonant frequency was found to be 141.39Mhz. This frequency is entered into a signal generator whose output is coupled to the RF cavity. The pickup signal from the other end of the cavity is amplified and fed into a mixer with the signal from the generator. The diagram of the bead perturbation setup is shown in Appendix 3. The beadpull test set uses a double balanced mixer (DBM) as a phase error detector to phase lock the synthesized frequency source to the cavity.<sup>2</sup> This is done by comparing a sample of the drive signal to the pickup from the cavity. The two signals entering the mixer are adjusted, with a phase shifter, so that the reading on the output of the mixer is 0 volts DC when there is no perturbation to the cavity. The output is then used to drive the voltage controlled oscillator (VCO) to maintain a zero phase error at the DBM. The voltage required to do this is proportional to the frequency shift of the cavity due to the perturbation introduced. This voltage is read by an oscilloscope via Labview. This voltage is directly proportional to the frequency to which the VCO in the signal generator was driven to maintain zero phase error at the mixer. In order to directly relate this change in voltage with a shift in frequency, a calibration sequence programmed a set of three frequency steps (5kHz, 10kHz, 15kHz) to the signal generator. See Figure 1 for an example of the calibration sequence of the metal sphere. The resulting oscilloscope reading is then stored in memory.

## Calculations

The output data from Labview was arranged in two columns, consisting of time(position) and voltage(frequency) data, and entered into MATHCAD where the remaining calculations

**Figure 1 Calibration Sequence of Metal Sphere**

were done. See Figure 2 for the graph of output data for the metal sphere.

The value of  $\epsilon_r$  for the ceramic sphere was found to be 9.7. In the case of the metal sphere,  $(\epsilon_r+2)/(\epsilon_r-1)$  drops out of the equation. The beadpull was done on axis for the fundamental mode and it was assumed that the magnetic field is zero in the gap. Thus the equation for  $\delta\omega_0/\omega_0$  of the metal sphere reduces to:

$$\frac{\delta\omega_0}{\omega_0} = \frac{3\epsilon_0 E_0 E_0^*}{4U} \Delta V$$

The perturbing volume,  $\Delta V$ , for the ceramic sphere equals the volume of the entire sphere minus the volume of the hole. However, the volume of the hole in the metal sphere was

**Figure 2 Output Data for Metal Sphere**

neglected because the electric field goes to zero inside a hollow metal sphere. The length,  $l$ , of the cavity, refers to the length of all the field regions over which the integration is performed. Since the data is taken as a function of time, and must be converted to dimensions of length,  $l$  was found by taking the number of seconds per reading set on the scope and multiplying it by the number of readings in the beampull data, and then multiplying it by the speed in which the sphere was moving. The accuracy of this measurement is maintained by using a stepper motor with a constant and highly repeatable number of steps per second.

As can be seen from the MATHCAD calculations in Appendix 4, the R/Q value for the ceramic sphere was  $70.137\Omega$ . Similar calculations were performed for the metal sphere resulting in an R/Q value of  $70.22\Omega$ . Therefore, the metal sphere differs from the reference value of  $69.02\Omega$  in SUPERFISH by only 1.7%, while the ceramic sphere data differs by 1.6% which demonstrates that the bead perturbation results are in excellent agreement with our computational results. If the magnetic field in the gap was non-zero, a value of R/Q less than SUPERFISH would have resulted. A non-zero magnetic field could be caused by a beadpull that is not exactly on axis, thereby causing a reduction in the measured frequency shift.

The quality factor, Q, of the system was found on a network analyzer. Two methods were employed to find the value of Q. A Smith Chart (Appendix 5) was utilized to find the unloaded Q of the cavity. The unloaded  $Q_0$  includes only those losses in the cavity alone. A log magnitude scale (Appendix 6), on the other hand, was used to find the loaded  $Q_L$ , which includes all sources of dissipation. The relation between the various Q's is:

$$\frac{1}{Q_L} = \frac{1}{Q_0} + \frac{\beta}{Q_0}$$

Since the cavity was found to be undercoupled, the value of  $\beta \ll 1$ . From this, the value of  $Q_L$  should be comparable with that of  $Q_0$ , but slightly smaller. Usually it is the value of  $Q_0$  that is used to find the shunt impedance, but since our measured value of  $Q_0$  was very similar to  $Q_L$  but still smaller, we took the average of the two (1,891) as our overall value of Q. As a result, the shunt impedance of the cavity was found to be  $133k\Omega$ . This departure from the theoretical value is due to additional losses in the test cavity that are not taken

into account by SUPERFISH. These losses are due to the cavity's rf joints and to the substitution of brass for copper in many sections of the cavity which lowers the conductivity. For the actual 26MHz accelerating cavity, the measured  $Q$  is  $\approx 85\%$  of the theoretical value and a closer agreement between calculated and measured shunt impedance is expected.

## **Conclusion**

$R/Q$  of an rf cavity was measured using the bead perturbation technique and compared with computational (SFISH) results. The agreement, to within 2% confirms the reliability of the approach for measuring  $R/Q$  of high  $Q$  structures. Future work will include automation of the data reduction utilizing Labview, a program development application which uses a graphical programming language to create programs in block diagram form. Another task will be designing a low-pass filter on the output of the DBM in order to reduce noise to provide a better signal to noise ratio in larger cavities where the frequency shifts to be measured are smaller.
